This is an author-produced manuscript that has been peer reviewed and accepted for publication in Language, Speech, and Hearing Services in Schools (LSHSS). As the “Papers in Press” version of the manuscript, it has not yet undergone copyediting, proofreading, or other quality controls associated with final published articles. As the publisher and copyright holder, the American Speech-Language-Hearing Association (ASHA) disclaims any liability resulting from use of inaccurate or misleading data or information contained herein. Further, the authors have disclosed that permission has been obtained for use of any copyrighted material and that, if applicable, conflicts of interest have been noted in the manuscript.

Abstract

Purpose: The purpose of this investigation was to conduct an evidence-based systematic review (EBSR) of peer-reviewed articles from the last 30 years about the effect of service delivery model on speech-language intervention outcomes for elementary school-age students.

Method: A computer search was conducted of electronic databases to identify studies that addressed any of 16 research questions. Structured review procedures were used to select and evaluate data based studies that used experimental designs of the following types: randomized clinical trials, non-randomized comparison studies, and single-subject design studies.

Results: This EBSR revealed a total of 5 studies that met review criteria and addressed questions of the effectiveness of pullout, classroom-based, and indirect consultative service delivery models with elementary school-age children. Some evidence suggests that classroom-based direct services are at least as effective as pullout intervention for some intervention goals, and that highly trained SLP assistants, using SLP-prepared manuals to guide intervention, can provide effective services for some children with language problems.

Conclusions: Lacking adequate research-based evidence, clinicians must rely on reason-based practice and their own data until more data become available about which service delivery models are most effective. Recommendations are made for an expanded research agenda.

Key Words: Service delivery models, pullout, classroom-based, indirect-consultative, evidence-based practice.
The choice of effective service delivery options is a major concern for school-based speech-language pathologists (SLP) as they serve on teams developing Individual Education Plans (IEP) for students with special needs. A service delivery model can be conceptualized as an organized configuration of resources aimed at achieving a particular educational goal. It must address questions of where service is to be delivered, by whom, and in what dosage. More specifically, IEP teams must identify the best mixture of personnel, materials, specific instructional or intervention procedures, the schedule and intensity for provision of services (e.g., dosage), the settings in which intervention services will be delivered, and the direct and indirect roles service providers will assume (Bennett, 1988; Cirrin & Penner, 1995).

As part of the current climate of accountability, SLPs face mandates to apply evidence-based practice (EBP) when making assessment and intervention decisions (Individuals with Disabilities Education Act of 2004 [IDEA]). EBP has been defined as “the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients...[by] integrating individual expertise with the best available external clinical evidence from systematic research” (Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996, p. 71). The American Speech-Language-Hearing Association (ASHA, 2004, 2005a, 2005b) has conceptualized the goal of EBP as the integration of (a) clinical expertise, (b) best current external evidence, and (c) client values to provide high-quality services that reflect the values, needs and choices of students and families served by SLPs.

The purpose of this investigation was to systematically evaluate peer-reviewed articles from the last 30 years to evaluate the effect of service delivery model on speech-language intervention outcomes for elementary school-age students. An evidence-based systematic review (EBSR) is a comprehensive overview of the scientific literature on a specific clinical question (in
this case, a set of 16 related questions), which is conducted using systematic procedures and explicit criteria to reduce bias, resulting in a summary report of the extent to which various treatment approaches are supported by research evidence (ASHA, 2004). A systematic review identifies common themes and gaps in the literature without using the statistical techniques that are employed in a meta-analysis.

In the absence of research evidence, service delivery decisions must be based on other criteria, often guided by tradition or expert opinion. Traditionally, SLPs in schools have used pullout rooms as settings for providing speech-language (S/L) intervention services in schools. "Pullout" typically refers to settings outside the regular or special education classroom where students receive individualized intervention. According to 2008 School Survey data (ASHA 2008), the pullout model continues to be the most prevalent model used by school practitioners in elementary schools. The summary report for that survey indicated that “Overall, clinical service providers spent an average of 22 hours each week in traditional pull-out service, 5 in classroom- or curriculum-based classrooms, 4 in self-contained classrooms, 3 in collaborative consultation, and 1 in a resource room” (p. 8).

Over the past 30 years, efforts have been made to develop, implement, and evaluate more inclusive alternative service delivery models for providing intervention services to students with S/L impairments. Alternative service delivery models for students with S/L impairments vary in design but often share the goal to enhance the curricular relevance of S/L intervention by altering the where and by whom characteristics of service delivery. This includes a) moving the setting of intervention from a separate therapy room into the student's ongoing educational experiences, and b) expanding the traditional, direct service provider role of the school-based SLP to include consultation and other indirect activities. A number of reports appear in the literature describing

Classroom-based models are described as those in which SLPs provide S/L intervention to individuals or to small groups of students in their general and special education classroom settings, or they may team teach with general and special education classroom teachers using lessons and scaffolding that integrate S/L intervention with instruction in the regular curriculum (e.g., Brandel, 1992; Buttrill, Niizawa, Biemer, Takahasbi, & Hearn, 1989; Christensen & Luckett, 1990; Despain & Simon, 1987; Dodge & Mallard, 1992; Ferguson, 1992; Nelson, Bahr, & Van Meter, 2004; Norris, 1989; Norris & Hoffman, 1990; Prelock, 2000; Prelock, Miller & Reed, 1995; Simon, 1987; Ukrainetz, 2006). Other alternative models of service delivery involve more indirect provider roles for SLPs. For example, SLPs consult with classroom teachers (or parents) who, in turn, provide the intervention to students (or their children) in their classrooms (or homes), either in addition to or in lieu of direct SLP services (e.g., Creaghead, 1990; Damico, 1988; Damico & Nye, 1990; Dyer, Williams, & Luce, 1991; Gruenewald & Pollak, 1990; Marvin, 1987; Prelock, 2000; Silliman, Wilkinson, Belkin & Hoffman, 1991; Simon, 1987). A different form of indirect service delivery model involves supervision by a
certified SLP of speech-language assistants as they implement selected face-to-face direct services. This model was evaluated in one large research trial conducted in the United Kingdom (Boyle et al, 2007). The other key service delivery model component (beyond questions of where and by whom service is delivered) is termed “dosage,” influenced by the medical roots of EBP. McCauley and Fey (2006) defined dosage as the frequency and intensity with which treatment is delivered (but see Warren, Fey & Yoder, 2007, for a review of how intervention intensity has been defined in the literature).

Even as inclusive classroom-based and consultative intervention approaches have become accepted and endorsed by professional organizations of the disciplines that work in school settings (McCormick, Frome Loeb & Schiefelbusch, 2003), concerns have been raised about limitations of classroom-based and consultation service delivery models for S/L intervention (Beck & Dennis, 1997; Ehren, 2000; Elksnin & Capilouto, 1994; Kavale, 2002; Law, Lindsay, Peacey, Gascoigne, Soloff, Radford & Band, 2002). In addition, some authors suggest that agencies may place children with disabilities in inclusive settings without full consideration of the unique and specific needs of each child (e.g., Westby, Watson, & Murphy, 1994), and SLPs continue to report difficulties with implementing collaborative consultation models in classrooms (Achilles, Yates, & Freese, 1991; Russell & Kaderavek, 1993).

METHOD

Literature Search Procedures

A systematic search of the literature was conducted between September 2007 and February 2008. Twenty-seven electronic databases were searched using a total of 55 expanded key words related to service delivery and frequency and intensity of speech-language pathology
services (see Appendix A for key words). Electronic databases included CINAHL, Centre for Reviews and Dissemination, EMBASE, ERIC, Evidence-based Medicine Guidelines, Education Abstracts, Exceptional Child Education Resources, Health Source: Nursing, HighWire Press, Linguistics Language Behavior Abstracts, Medline, National Library for Health, National Rehabilitation Information Center, Neurosciences Abstracts, PsycBITE, PsycINFO, PsycArticles, Psychology and Behavioral Sciences Collection, PubMed, Science Citation Index, REHABDATA, Social Science Citation Index, Social Services Abstracts, SUMSearch, Teacher Reference Center, TRIP Database, and the Cochrane Database of Systematic Reviews. These databases were selected because they are among the larger databases available and were judged most likely to contain articles on communication sciences and disorders in general as well as in response to the research questions. We excluded databases that were not relevant to our population (e.g., gerontology). Electronic searches of all ASHA journals, as well as hand searches of references from all relevant articles, also were completed for this EBSR.

**Criteria for Inclusion in Systematic Review**

We reviewed all studies that met the following selection criteria:

1. Studies had to contain original data that specifically addressed one or more of the 16 clinical questions presented in Table 1.

   **Rationale.** The questions that were used to frame the current review were specific to the elementary school age-range (from 5 to 11 years), and were divided into sets to ask separately about the effects of type of service delivery model and the frequency and intensity with which service is delivered. In constructing these questions, we used the format adopted by ASHA’s National Center for Evidence-Based Practice in Communication Disorders (N-CEP) for systematic reviews. Thus, each question specifies a population (e.g., school-age
children ages 5-11 years), an intervention (e.g., service delivery model), and a specific clinical outcome (e.g., vocabulary). Outcome measures were selected to represent the range of therapy targets that, in the experience of the authors, were typical and appropriate for elementary students with speech and language problems. Also, we wanted to select clinical outcomes that are commonly measured by standardized tests of speech and language or by functional real-life measures of speech and language performance (e.g., speech, language, conversational samples and observations).

2. Studies had to be published after 1975 in peer-reviewed journals, and written in English. **Rationale.** The authors reasoned that our three-decade time frame was sufficient because a meta-analysis of speech-language intervention by Law, Garrett, and Nye (2004) revealed that only one of seven articles on expressive language intervention, none of the ten articles on vocabulary intervention, and none of the two articles on receptive language intervention were published prior to 1985. In addition, prior experience suggested that articles older than thirty years generally do not include enough methodological detail for the reader to be able to replicate the intervention or to compute effect sizes.

3. Studies that were included in the review had to use one of the following design types: randomized clinical trials (RCTs), meta-analyses of RCTs, and systematic reviews of RCTs; nonrandomized comparison studies; or multiple-baseline single-subject design studies. Studies had to hold the type of intervention constant and only vary the service delivery model or dosage (i.e., frequency and intensity) of SLP services. A SLP had to be
involved in the service delivery. Descriptions of service delivery models without data based on objective measures of treatment outcomes were not included.

**Rationale.** In RCTs, the investigator actively compares treatment and control groups that have been created by randomly assigning participants to the groups. Nonrandomized comparison studies contrast the outcomes of treatment groups by comparing outcomes for students who were matched to each other on a particular variable or who were assigned to groups on any basis other than randomization. We also included multiple-baseline single-subject design studies because they demonstrate causality in a manner that is generally considered to be reliable and valid. Treatment methods were not allowed to vary in addition to the service delivery model to make it possible to attribute any differential outcomes to the service delivery model alone.

4. Studies had to include children ages 5 to 11 years (i.e., elementary school-age children, usually in grades K - 5) with speech-language impairment as either a primary disability or secondary disability.

**Rationale.** Studies on speech-language service delivery models used with preschool children (under the age of 5) or older students (ages 12 and above) were not included because of the authors’ intent to focus on elementary-age students and constraints on time and resources. Time and resource constraints, along with focus, also provided the rationale for not including studies of service delivery models used with “at risk” students (without identified speech-language disabilities) in general education settings, or studies of students with learning disabilities delivered by interventionists not clearly identified as SLPs. We wanted to include studies of students with “secondary” language and communication
problems related to autism spectrum disorders, developmental cognitive disabilities,

general developmental delays, hearing impairment, and other disabilities, because school

SLPs often have questions about appropriate models for delivering speech-language

services to these students.

**Articles Identified and Accepted orRejected**

Using the search terms summarized in Appendix A, 462 citations were originally identified

for review based on article abstracts. Two authors, blinded from one another’s results, reviewed

each abstract and initially identified (with 95% agreement) 255 abstracts as potentially meeting the

inclusion criteria. Full-text articles of these studies were reviewed, which resulted in an additional

250 articles being excluded because they did not directly address one or more of the clinical

questions, did not use an experimental or quasi-experimental design, did not hold the intervention

constant and only vary the service delivery model, did not report original data, did not include a

SLP in the service delivery, or had participants outside of our specified age range. A total of 5

studies remained that met all inclusion criteria. They constituted the corpus for this EBSR. A log of

rejected studies including the reasons for exclusion is available from the authors upon request.

**Quality Appraisal Procedures**

Two authors, blinded to one another’s results, assessed each study for methodological

quality (with 95% agreement) in the following areas: study protocol description, assessor

blinding, sampling/allocation, evidence of treatment fidelity, significance, precision and

intention to treat (when applicable). “Intention to treat” is defined as:

“An analysis of a randomized controlled trial where participants are analyzed according to

the group to which they were initially randomly allocated, regardless of whether or not they

had dropped out, fully complied with the treatment, or crossed over and received the other
treatment. Because it maintains the original randomization, an intention-to-treat analysis contributes to the internal validity of a treatment study.” (ASHA, 2005b)

For each study a quality score was determined based on the number of indicators that met the highest level of quality in each area. A study received a point for each indicator meeting the highest level of quality (see Table 2). For controlled trials, all seven quality indicators were relevant, leading to a maximum quality score of 7. For all other study designs, where an intention to treat analysis was not applicable, the highest quality score was 6.

Each critical appraisal was reviewed by at least two randomly chosen authors. Any discrepancies in ratings between authors were resolved via consensus. A final synthesis of the body of scientific literature was compiled into an evidence table based on the study quality indicator score and corresponding clinical question.

[Insert Table 2 about here]

**Data Extraction Procedures**

The data extraction tool used in the present EBSR was based on careful consideration of the data categories that, in the authors’ experience, were relevant to the study of service delivery models. Also, we attempted to be consistent with published guidelines for appraisal of the quality of systematic reviews (Schlosser, Wendt & Sigafous, 2007). Final data coding categories included citation, participant characteristics, eligibility criteria (e.g., eligibility for specific disability categories, such as number of standard deviations below mean on norm-referenced tests), specific communication problem(s), service delivery model(s), treatment schedule and amount and duration of treatment (e.g., dosage factors as per suggestions of Warren, Fey and Yoder, 2007), intervention, outcome measures and major findings, statistical significance, effect
size, limitations of the study and caveats to generalization of study results. These coding categories comprise the column entries in the main results table (Table 3). Each author was randomly assigned to be either “lead reviewer” or “backup reviewer” for data extraction for each article in the EBSR corpus. Any disagreements on article summaries were resolved through a discussion with all authors, and discrepancies were resolved by consensus.

**Effect Size Calculation Procedures**

Effect size (ES) is a method of quantifying the effectiveness of a particular intervention, relative to some comparison intervention. In this case, it quantifies the size of the difference between outcomes for two groups who received essentially the same treatment, but in the context of different service delivery models. See Schuele and Justice (2006) for a tutorial on the interpretation of effect size.

When possible, we report the effect sizes that were reported in the articles. When effect sizes were not reported, but sufficient data (i.e., pre- and posttest means and standard deviations) were provided by the authors, we report effect sizes that we either calculated or estimated based on results of ANOVAs or t-tests. Group effects were calculated using Cohen’s $d$, with the formula: $M1$ (mean posttest score for experimental group) – $M2$ (mean posttest score for control group) / pooled standard deviation. With this method, an effect size of 0.8 or greater is considered to be large, an effect size of 0.5 is medium, and an effect size of 0.2 or less is small (Cohen, 1988).

Effect sizes for single-subject designs (in which a single child’s performance is compared over one or more baseline periods with treatment periods) are calculated by computing the percentage of non-overlapping data (PND). This value indicates the percentage of data points during the treatment phase that exceed the most extreme data point in the baseline phase. With
this method, higher percentages of non-overlapping data indicate stronger effects (90% = very effective treatments; 70%–90% = effective treatments; 50%–70% = questionable; <50% = ineffective) (Scruggs & Mastropieri, 2001). However, PND was not calculable for the one single-subject study included in this systematic review (Kohl, Wilcox & Karlan, 1978) because of insufficient data.

RESULTS

Of the five studies that met the inclusion criteria, three addressed the effect of SLP service delivery model on vocabulary skills (Question 1), one examined the influence of service delivery model on functional communication (Question 2), and three addressed the effect of service delivery on language or literacy outcomes more broadly (Question 5). This total exceeds five because several studies addressed more than one of the clinical questions. No studies were found relevant to the remaining 13 clinical questions. Table 3 provides the results of the EBSR, including descriptions of the intervention and participants reported in the studies, major outcomes, statistical significance, and effect size estimates. Table 4 indicates the methodological quality ratings for each study.

Clinical Question 1: What is the influence of the SLP service delivery model on vocabulary?

Three studies were identified that addressed this question (see Table 3). Boyle et al. (2007) compared four different models of SLP service delivery for children with speech and language impairment including: individual SLP treatment (direct); group SLP treatment (direct); individual treatment provided by an SLP assistant (indirect consultative); and group treatment
provided by an SLP assistant (indirect consultative). This study was conducted in the United Kingdom, where services to students with communication disorders are provided via health service mechanisms rather than as part of school systems. Looking at methodological quality ratings for this study (see Table 4), all seven quality indicators were applicable and the study by Boyle et al. met the highest level for every methodological quality indicator assessed. Boyle et al. found minimal differences in effect size estimates for student outcome measures (standardized test scores) between direct services provided by SLPs and indirect service provided by SLP assistants ($d$ values less than .15). In addition, effect size estimates for differences in student outcome measures between group and individual therapy provided by SLPs and by SLP assistants were small (post-treatment $d = -0.10$; 12-month follow-up $d = 0.01$). These finding led the authors to conclude that for vocabulary (measured by a standardized test) services provided by a SLP assistant were as effective as services provided by certified SLPs for children with primary language impairments, and individual and group therapy were equally effective regardless of which type of provider was delivering the service.

Kohl, Wilcox and Karlan (1978) used a single-subject design to compare pullout individual service by a SLP with service provided in a classroom by a special education student teacher to a group of three students with cognitive disabilities. Looking at methodological quality ratings for this study (see Table 4), one quality marker (intention-to-treat analysis) was not relevant since this was a single-subject design. This report provided adequate descriptions of the study protocol but was lacking in other areas such as assessor blinding and evidence of treatment fidelity. Results indicated that each student in the daily small group classroom sessions reached criterion sooner on their directly trained manual signs (signs for 12 food items produced in a test-like task) than they did on a comparable set of signs trained in individual therapy sessions. Also, generalization probes
indicated that signs generalized best in the settings in which they were trained. Kohl et al. (1978) did not provide sufficient data to analyze the findings statistically, nor were we able to compute effect size estimates using the PND method previously described. This makes it difficult to determine if there were any practical effects related to the use of different service delivery models as described in this study.

The third study that addressed this question was conducted by Throneburg et al. (2000). They compared the effects of three service delivery models for teaching curricular vocabulary skills to students in kindergarten through third grade. The models were described as follows: (1) a collaborative classroom model, in which team teaching was provided by the SLP and classroom teacher, (2) a classroom-based model, in which the SLP provided intervention to a class of students without collaboration with classroom teacher, and (3) a traditional pullout model. The researchers used a high quality design, including random assignment of participants to condition (see Table 4), increasing the level of confidence in the evidence gathered in this investigation. These authors reported that children in a collaborative classroom condition exhibited greater gains in curricular vocabulary compared to children in a classroom-based condition in which SLPs taught alone and compared to children receiving pull-out direct therapy from a SLP. Effect sizes ranged from $d = 0.3$ to $1.65$ with students receiving services through a collaborative classroom model showing the greatest gains ($d = 1.65$) compared to those who received services in a classroom-based model without collaboration, and statistically significant, but more modest gains ($d = 0.3$) when compared with pullout services. Traditional pullout services also had a positive effect ($d = .76$) when compared with classroom-based treatment that did not incorporate collaboration with the classroom teacher. Our analysis and calculation of estimated effect sizes for this investigation
suggest a clear advantage for classroom-based team teaching for improving children’s curricular vocabulary knowledge versus pullout intervention.

Clinical Question 2: What is the influence of the SLP service delivery model on functional communication?

One study was identified that addressed this clinical question (Howlin, 1981). Table 4 indicates the methodological quality ratings. We judged that Howlin (1981) provided an inadequate description of the type, amount and content of training parents received or the intervention provided to their children at home; however, the author did report sufficient data to calculate statistical significance and effect sizes. In this study the effects of language treatment provided by parents to their children with autism at home were compared with effects for children who received “irregular outpatient” service in a hospital. Our computation of effect size estimates revealed that service delivery had little to no effect on participants’ functional communication skills. When compared to children who had hospital-based outpatient treatment, the home-based treatment provided by trained parents had a small positive effect on the number of comprehensible utterances ($d = 0.38$) and reduction in the percent of non-communicative and meaningless verbalizations ("non-verbal utterances") ($d = 0.35$), but minimal effect on the percent of socialized spontaneous utterances ($d = 0.11$) or the percent of echolalic/autistic utterances (e.g., immediate echolalia, delayed echoes, stereotyped remarks, repetition of self) ($d = -0.21$). Unfortunately, these results provide little information on the relative effectiveness of indirect service (i.e., parent training) compared to direct service (i.e., hospital-based) because descriptions of both service types were inadequate. Data comparing indirect service (parent training) to the no-service control condition were not relevant to the current systematic review.
because comparison of any service delivery model with no treatment does not specifically address the role of type of service delivery model on student outcomes. Although it passed through the filters for the current review, the Howlin study might better be considered an “exploratory” study (Mullen, 2007), providing some evidence that training parents to implement a specific language program at home with their children with autism shows promise of being efficacious.

**Clinical Question 5: What is the influence of the SLP service delivery model on language or literacy?**

Three studies (see Table 3) contributed data to address this clinical question. Bland and Prelock (1995) compared the effectiveness of direct pullout service by a SLP to a classroom-based collaborative service model team-taught by the teacher and SLP. In terms of methodological quality (see Table 4), while Bland and Prelock provided an adequate description of the study protocol and reported the statistical significance of the findings, they did not provide enough statistical data for us to calculate effect size estimates. Although the authors stated that participants in both groups improved overall language performance over several years (though no individual or group data were reported), their statistical analysis revealed no differences between groups on student outcome language measures with the exception of “number of intelligible and complete utterances” (transcribed using the software program *Systematic Analysis of Language Transcripts* [SALT]; Miller & Chapman, 1986) favoring the collaborative condition. Due to methodological limitations, our analysis suggests that this study provides only minimal support for the authors’ conclusion that the use of a classroom-based collaborative service model had positive effects on the language production of participants with communication disorders.
The two additional studies that addressed this question have been described previously in the section on “Clinical Question 1”. Boyle et al. (2007) compared different versions of pullout models on standardized measure of receptive and expressive language—group versus individual therapy, and direct (services delivered by SLP) versus indirect therapy (services delivered by SLP assistant). Results from Boyle et al. (2007) indicated that service delivery had no effect on the language outcomes ($d \leq 0.15$) as measured by the $\text{CELF-3}^\text{UK}$ (Semel, Wiig & Secord, 2000).

Howlin (1981) examined the effects of indirect (trained parents delivering treatment at home) to direct (clinicians delivering treatment in hospital outpatient settings) on formal and informal measures of language use for children with autism. The six effect sizes calculated from Howlin (1981) ranged from $d = -0.45$ to 0.08. In this study, treatment provided in an outpatient setting (control group) had a small positive effect over treatment provided by trained parents (experimental group) on mean length of utterance ($d = -0.39$), number of morphemes ($d = -0.33$), and the comprehension subtest ($d = -0.45$) of the $\text{Reynell Developmental Language Scales} (\text{RDLS})$ (Reynell, 1969). The type of service delivery model employed had no discernible effect on the number of sentence transformations ($d = 0.08$), number of phrases ($d = 0$), or on the expressive language subtest of the $\text{RDLS} (d = -0.18)$.

**DISCUSSION**

Along with the authors of this report, SLPs who provide intervention to students in schools may find the results disconcerting. It is both a matter of concern and illuminating that our systematic search for experimental evidence revealed only five studies that met our criteria. The unavoidable conclusion is that clinicians have little research evidence on which to base decisions about service delivery options. Given the small number of studies, no conclusions are
justified even regarding trends in the research literature for informing school service delivery choices. This is not a situation in which high-quality evidence is available to indicate that specific service delivery models are not effective, or that one model is clearly better than another. Rather, this is a situation in which insufficient high-quality evidence is available to support any strong conclusions about differential benefits of service delivery models used in school settings.

We also had some concerns about characteristics of the five studies that did meet our criteria that might be critical for their interpretation but were not necessarily highlighted by the structured review. Our point is to raise awareness of the challenges in conducting applied research in school settings so more and better studies can be designed in the future. The study by Boyle et al. (2007) of “direct” and “indirect” individual and small group pull-out services, in particular, must be interpreted in light of the several important factors. First, “indirect service” was operationally defined narrowly by this study’s authors as the use of highly trained SLP assistants to implement intervention. As conceptualized by ASHA (2002) indirect service includes a number of SLP workload activities in addition to training and supervising SLP assistants (for example, consulting with general education and special education teachers on the use facilitative communication behaviors in their classrooms in order to positively affect their students’ functional communication abilities). Second, the SLP assistants had undergraduate degrees in psychology, had undergone an extensive training program, and were using a detailed, standardized manual developed by SLPs to guide their intervention activities. This level of training and support appeared to be a critical factor in the fidelity with which the assistants provided language treatment, and thus to the effectiveness of their intervention service. We expect that these conditions would need to be replicated in order to obtain similar results in
additional studies. Third, group size varied between 2 and 5 students in the investigation, but group intervention was treated as a single variable, which confounds the interpretation that student communication outcomes are not affected by size of the intervention pullout group. Fourth, the primary student outcome measures investigated by Boyle et al. were standardized test scores (e.g., *British Picture Vocabulary Test*), leaving open the question of whether similar results would occur with more authentic measures of language use and function that are coordinated closer to the school curriculum.

The results of the study by Kohl et al. (1978) likewise must be interpreted cautiously. Limitations of that study included a small number of participants, and relatively narrow language targets (i.e., signs for 12 food items). Another limitation was the fact that the trainer was not held constant in both conditions (i.e., an SLP provided intervention in the individual pullout condition and a student teacher in the classroom group condition).

Although the study by Throneberg et al. (2000) included many positive characteristics, it also exemplifies some of the challenges of studying service delivery in the real-life contexts of schools. As an example, the researchers emphasized the importance in the study of having assigned time during the school day for joint planning between the teacher and SLP (approved by administrators and with substitute teachers), which was funded by a grant. Although this may have been a critical “active ingredient” to the success of the model in this study, it was not investigated directly as an experimental variable, and the extant literature on classroom and collaborative service delivery models has not experimentally verified this or other key ingredients of complex alternative delivery models.

**Relationship of Current Findings to Other Systematic Reviews**
Two related evidence-based systematic reviews (Cirrin & Gillam, 2008; McGinty & Justice, 2006) that have appeared previously in the literature each included at least one of the studies included in the current review. Cirrin and Gillam (2008) included the study by Throneburg et al. (2000) in their EBSR of language intervention practices for school-age children with spoken language disorders. That review excluded studies with participants who were not classified as “specific language impaired” and studies with preschool children. The study by Boyle et al. (2007) was published after Cirrin and Gillam went to press, accounting for differences between the evidence corpus in this study and in the present EBSR. McGinty and Justice (2006) found three studies (Throneburg et al., 2000; Valdez & Montgomery, 1996; Wilcox, Kouri, & Caswell, 1991) that met their inclusion criteria (which included preschool children) in their attempt to answer the clinical question comparing classroom-based to pull-out language intervention (individual or group), as shown by improvements in language skills in the areas of phonology, morphology/syntax, pragmatics, and/or vocabulary.

Analysis of Throneburg et al. (2000) by Cirrin and Gillam (2008) and McGinty and Justice (2006) yielded similar results to the analysis in the present EBSR. For the two additional studies on service delivery models identified by McGinty and Justice (2006), their analysis revealed that Valdez and Montgomery’s (1996) findings (showing no differences in child outcomes when comparing classroom-based and pullout conditions) needed to be interpreted with caution due to limitations of the study’s methodology. McGinty and Justice reported that methods used by Wilcox et al. (1991) led to greater confidence that classroom-based team teaching by the SLP and special education teacher could be credited for a large positive effect in preschool children’s productive vocabulary use compared to a pullout condition. McGinty and Justice concluded that “taken together, the convergent findings from Throneburg et al. (2000)
and Wilcox et al. (1991) suggest an advantage for classroom-based team-teaching models over pullout intervention, at least in the domain of vocabulary” (p. 12). We were more cautious about concluding such an advantage because only one of these two studies was conducted with elementary-age children and was included in the current review.

**Excluded Studies with Implications for Informing Clinical Practice**

As we searched for articles that met our inclusion criteria, it became apparent that a number of studies did not meet our criteria but still included empirical evidence that could help inform clinical practice. Many of these articles fall into the category of “exploratory” studies (Mullen, 2007) that address the feasibility of specific intervention approaches, but do not use an experimental or quasi-experimental design with control groups (as required for the current review). Other articles were excluded because participants were outside of our specified age range (e.g., preschool), had not been identified with speech-language impairments, or because it was not clear that the service providers were SLPs. Each author of the present EBSR was invited to list those excluded studies that, in their opinion, provided empirical evidence that could help inform decisions on service delivery models. No attempt was made to compute inter-rater reliability for these selections. In Appendix B we provide the authors’ original abstracts of these articles that readers can consult for additional guidance in their evidence-based decision-making concerning treatment contexts, along with the reasons they were rejected from the present EBSR.

**Limitations**

Limitations of the present systematic review should be considered by SLPs who are reminded to interpret our findings with caution. It is important to note that this EBSR focused only on elementary-aged students identified with a communication disorder, which limited the number of studies that could be included. This EBSR did not include studies of speech-language
service delivery models with preschool-aged students, older students (12+ years) or students considered “at risk” but without identified language disabilities. The net result was that this systematic review did not capture completely the range and scope of the extant research currently available on alternative service delivery models for speech and language intervention. Other studies addressing the effects of SDM with these populations (see Appendix B) may have provided SLPs with additional evidence or insights to assist with clinical decision making.

Second, the choice of clinical questions in this review necessitated limiting included studies to RCTs or other experimental designs. Since other study designs could not answer the proposed clinical questions, we may have excluded sectors of the practice of speech-language intervention (Johnston, 2005). Thus, it is probable that some evidence that could be quite useful to school clinicians did not meet the inclusion criteria for this review. However, scientific rigor is essential if EBSRs are to have comparable meaning. Also, confidence in the stability and validity of results is enhanced when studies are designed to directly assess causal relationships.

Additional limitations stem from the number and quality of the studies that were identified for our EBSR. Pring (2004), critiquing the lack of appropriate outcome research in speech and language therapy, has argued that the shortage of research and the difficulties of conducting studies of the necessary quality mean that few studies qualify for inclusion, thus rendering the results of systematic reviews of little value. With only five studies serving as the corpus for our review, and weaknesses in the studies themselves, clinicians are advised to exercise caution when interpreting the results.

**Clinical Implications**

Based on the results of our EBSR, direct S/L intervention procedures implemented in classroom settings have not been put to adequate experimental tests to determine their
effectiveness in facilitating development of S/L abilities in school-age children with disabilities. However, some evidence suggests that classroom-based direct speech-language services are at least as effective as pullout intervention for some intervention goals (e.g., vocabulary) and that intervention in classroom settings may facilitate generalization of new skills to other natural settings. Little empirical information is available about the effectiveness of indirect consultative models in facilitating the acquisition of communication skills in elementary school-age children with speech-language impairments. It does seem clear that highly trained SLP assistants, supervised and directed by SLPs and using SLP-prepared manuals to guide language intervention, can provide effective services for some children with language problems. Some evidence also suggests that children with complex needs may benefit from services that include a parent training component.

SLPs must also provide services that are consistent with the requirements of federal policy. Service delivery models for students with disabilities are not directly addressed in the Individuals with Disabilities Education Act of 2004. Instead, IDEA states that children must be provided a free, appropriate public education in the least restrictive environment (LRE). LRE stipulates, “to the maximum extent appropriate, children with disabilities are educated with nondisabled children” (34 CFR 300.550). This implies the need for an array of environments and services that meet the evolving learning requirements of children with disabilities. In addition, federal regulations state “Placement decisions must be based on the individual needs of each child with a disability. Public agencies, therefore, must not make placement decisions based on a public agency’s needs or available resources, including budgetary considerations and the ability of the public agency to hire and recruit qualified staff” (The Federal Register, p. 46587).

**What should SLPs do given the paucity of external research evidence?**
Clinicians committed to evidence-based practice must consider the quantity and quality of research evidence supporting a specific service delivery model relative to the individual needs of each student and the practical constraints of practice in school settings. EBP does not require clinicians to use research evidence as the only basis for clinical decisions. In fact, it actually requires that clinicians consider research evidence in light of factors related to student, parent, and clinician beliefs and values, as well as the clinician’s expertise (Gillam & Gillam, 2006).

SLPs also must keep in mind that the most natural setting possible (i.e., LRE) must be used for intervention for students with disabilities. In addition, clinicians can use scientific thinking, theory and reason to back their instructional procedures when strong external evidence is not available (Stanovich & Stanovich, 2003). Lacking adequate research-based evidence, clinicians must rely on reason-based practice and their own data until more data become available.

Systematic reviews of the experimental literature on service delivery models, like the one reported in the present paper, will help SLPs in this EBP decision process as they attempt to find, synthesize, and evaluate the external evidence. However, given the paucity of evidence on the efficacy and effectiveness of alternative service delivery models for school-age children with speech-language disabilities, SLPs need to continue to turn to internal and client factors in their clinical decision making process. This means that SLPs in schools should evaluate the evidence on service models with particular attention to maximizing student participation in ecologically relevant intervention activities.

Further, SLPs can collect data on children in their own practices who received treatment via the same kind of service model over the course of several semesters. These data would suggest the range of outcomes that the SLP could expect for a specific service delivery model. SLPs must continue to evaluate the functional outcomes of the speech-language service delivery
models they choose by documenting instances in which their students demonstrate use of individualized language targets correctly (without prompts or cues) in natural speaking situations. In addition, clinicians should obtain information on changes in the type and amount of students’ functional language abilities in daily classroom activities from parents, teachers, and other professionals who work with the children on their caseloads (Gillam & Gillam, 2006).

In summary, until the research base expands and confirms the efficacy and effectiveness of specific service delivery models for the wide range of school-age students with communication problems, SLPs working in school settings will need to select service models carefully, monitor students’ progress on a regular and frequent basis, and validate the effectiveness of the intervention program for each student on their caseloads.

**Filling Gaps in the Evidence Base**

SLPs who work in schools need information from experimental or quasi-experimental studies that examine the effectiveness of the wide range of classroom-based and collaborative direct service models implemented for students with speech-language disabilities. We found no studies that met our criteria that investigated outcomes for students who received regularly scheduled face-to-face direct intervention services within their general or special education classroom compared with treatment of the same type and intensity in pullout settings. This was surprising given the amount of literature and expert opinion articles promoting classroom-based intervention models.

The authors recognize the challenges and barriers associated with conducting such research, including the fact that randomized assignment of students to treatment approaches must be explained to and accepted by parents, teachers, and school administrators, and even then, may violate individualized planning requirements of IDEA. On the other hand, lack of evidence on
Research is also needed to identify the optimal combination of service delivery variables to fit different needs of different students. Our evidence search failed to uncover any experimental studies that systematically investigated the factors that influence the success of classroom-based and indirect consultative models for delivering speech-language intervention. For example, studies are needed to identify such factors as the number of classroom opportunities needed for a student to increase performance of a particular communication skill (e.g., number of opportunities in a 30-minute lesson, in an hour, in a day, in a week, etc.), how SLPs can help teachers engineer classrooms to afford multiple opportunities to practice new language skills, and how language goals can be integrated efficiently into a classroom’s existing structure and routines, with realistic amounts of time invested by the classroom teacher and SLP.

Another major gap in the evidence is that no studies were found that met our criteria that examined the effectiveness of indirect consultative and “inclusive” service delivery models for communication intervention for populations with speech and language problems secondary to other primary disabilities (such as autism, developmental cognitive delay, or developmental delay). When a SLP serves students with these disabilities in the capacity of a related service provider in inclusive classrooms, a number of adults must work collaboratively to individualize students’ education programs, determine related services, and coordinate their activities to have
impact on students’ educational (and communication) outcomes (Giangreco, 2000). Given that current legislation, societal pressures, and professional policies often emphasize a philosophy and preference for inclusive settings for children with disabilities, SLPs and other IEP team members need evidence to indicate whether integrated communication services for these students yield better outcomes in curriculum-relevant communication skills than pullout sessions do.

Although it is common for educators and parents to assume that “more is always better”, there has been almost no systematic study of the effects of the frequency, number or length of S/L treatment sessions, treatment intensity, or how different schedules of service affect the communication performance of students with S/L or other primary disabilities (Warren, Fey & Yoder, 2007). This represents a major gap in the evidence on the dosage of intervention required to make significant progress on speech and language targets for school-age children who receive service in school settings. An example of this type of research was a study by Jacoby, Lee, Kummer, Levin, and Creaghead (2002), who determined the average number of treatment units needed to achieve improvements in functional communication for preschool children receiving individual therapy in a hospital setting. This study also provided some preliminary data on which children showed differential gains and needed more treatment units. Jacoby et al. found that younger children received the greatest benefit per units of therapy provided, and that children with lower initial functional communication abilities required more units of therapy to demonstrate improvement than children with higher initial ability levels. Research on the basic clinical question of the effects of intervention dosage on students’ functional language abilities is needed by SLPs who work in school settings with older children in grades K through 12. Readers are referred to Warren, Fey and Yoder (2007) for a detailed discussion and recommendations for research on differential treatment intensity in communication intervention.
Additionally, we were surprised to find that even the basic question of treatment efficacy for students in group therapy versus individual therapy remains largely unanswered for school-age children with a variety of speech-language disabilities. An exception was the Boyle et al. (2007) study reviewed in the present EBSR, which collapsed group sizes between 2 and 5 students as a single variable. With respect to research on group size, research reviewed in the ASHA technical report on workload and caseload size (ASHA, 2002) provides modest support for several clinical hypotheses: a) service provided to students in large groups appear to minimize opportunities for individualization of interventions, b) when instructed in smaller instructional group (3 or fewer), students with a wide range of disabilities are more engaged and have better outcomes, and c) among desired student outcomes, communication skills in particular appear to be positively influenced by small treatment group size, and negatively influenced by larger treatment group size (ASHA, 2002). Unfortunately, none of the studies reviewed in the school workload technical report used high quality experimental or quasi-experimental designs, which limits conclusions about the effect of group size on student communicative outcomes.

Our review of these studies raises questions about what types of evidence are appropriate measures for demonstrating the effectiveness of alternate service delivery models. In schools, SLPs are charged with not only facilitating improved fundamental language skills but also with providing therapy that enables students to progress in the general or special education curriculum. It is an open question whether measures of finite or discreet language skills (such as grammatical markers or improved performance on standardized tests) are appropriate for measuring the effectiveness of functional curriculum-related goals of school-based S/L intervention. Future studies of the effectiveness of classroom-based and indirect-consultative
service models must consider how best to measure student communicative outcomes most critical to success in school.

CONCLUSIONS

The current evidence base does not justify any broad conclusions about which service delivery models are preferable for which elementary school-age children with which specific communication needs. The optimal combination of service delivery variables, such as intervention setting, dosage, and service provider roles, is likely to differ for individual children. In addition, public education policy (IDEA 2004 in particular) requires that the choices for special education services be based on the specific needs of each student. Thus, IEP teams must rely more on reason than research for the time being in making service delivery decisions for individual students.

This systematic review of EBP of service delivery models for children with speech and language problems is a narrow sample of what needs to be done given the extensive scope of practice of communication disorders in schools. In general, the quantity and quality of research for informing EBP optimally in schools must be enhanced. Specifically, resources are needed for conducting studies on effective service delivery options for children (i.e., birth – 21 years) served by school-based SLPs. The results of this EBSR could serve as a stimulus for funding agencies such as the Institute for Educational Science of the U.S. Department of Education and the National Institutes of Health (e.g., the National Institute on Deafness and Other Communication Disorders and National Institute on Child Health and Human Development) to give priority to optimizing the research base supporting EBP for speech-language pathology service delivery models in schools.
Acknowledgments

The authors gratefully acknowledge the resources of the American Speech-Language-Hearing Association and the National Center for Evidence-Based Practice in Communication Disorders that made this EBSR possible, and particularly, contributions of Rob Mullen, Tobi Frymark and Hillary Leech.

<td>Rafferty, Piscitelli &amp; Boettcher (2003)</td>
<td>A study compared language development and social competence among 96 preschool children with disabilities in inclusive and segregated classes. Pretest ability was the strongest predictor of progress. Subjects in inclusive classes had higher posttest scores in language development and social skills, but more behavior problems, than peers in segregated classes.</td>
<td>Participants were preschool age; did not address clinical question</td>
</tr>
<tr>
<td>Roberts, Prizant &amp; McWilliam (1995)</td>
<td>The interactions of young children and their speech-language pathologist during out-of-class and in-class language intervention were compared for 15 children with disabilities attending a mainstreamed childcare center. Children were pair matched and randomly assigned to either in-class or out-of-class special services. After 3 months, treatment sessions were videotaped. The results indicated that some, but not all, aspects of both speech-language pathologists' and children's interactions differed during in-class versus out-of-class treatment sessions. During out-of-class sessions, speech-language pathologists took more turns than during in-class sessions. Children complied more with requests during out-of-class sessions and responded less to requests during in-class sessions. The results suggest that because in-class and out-of-class models have differential effects only on some aspects of clinician and child behavior, selection of service delivery models must be determined by a myriad of factors. Furthermore, these findings suggest that, in the absence of more conclusive data, it is premature to equate a particular mode of service delivery with a higher degree of treatment efficacy.</td>
<td>Participants were preschool age; did not address clinical question</td>
</tr>
<tr>
<td>Seifert &amp; Schwarz (1991)</td>
<td>The ability to understand and use basic concepts is a key to academic success. This study demonstrated that short-term, large-group basic concept instruction significantly improved the basic concept scores of children in Head Start as measured by the Boehm Test of Basic Concepts-Revised. The intervention combined direct instruction, interactive and incidental teaching techniques, and enabled the speech-language pathologist to serve children effectively.</td>

</tr>
<tr>
<td>Valdez &amp; Montgomery (1997)</td>
<td>This study was designed to address the paucity of empirical data regarding the outcome of treatment approaches for preschool children with communication disorders. Specifically, this study examined the differences in the effectiveness between the inclusion model of speech-language treatment and the traditional pullout model of speech-language treatment. African American children in an inner-city Head Start program with documented speech-language delays were randomly assigned to groups using the two treatment approaches. Results supported the research hypothesis that there is no significant difference between these two models of speech-language treatment. Findings suggest that the inclusion model is just as effective as a traditional pullout model in conducting speech-language services for children with mild, moderate and severe communication disorders.</td>
<td>Participants were preschool age</td>
</tr>
<tr>
<td>Wilcox, Kouri &amp; Caswell (1991)</td>
<td>This investigation focused on the effectiveness of classroom versus individual interventions in promoting initial lexical acquisition for young preschool children with language delays. Twenty children aged 20-47 months were randomly assigned to individual and classroom-based early intervention programs. Progress was measured in terms of children's spontaneous and productive use of the target items in treatment and home-based</td>
<td>Participants were preschool age</td>
</tr>
</tbody>
</table>
generalization settings at mid- and post treatment measurement points. Results indicated that use of target words as measured by treatment data was equal for children in the two intervention conditions. Differences were apparent when home generalization data were considered. Children in the classroom intervention condition demonstrated a greater degree of productive use of target words in the home generalization measures than did children in the individual intervention condition. The children also demonstrated differences in use of target words in treatment versus home settings. A fair amount of individual variation was apparent in lexical learning in each of the treatment conditions, and pretreatment cognitive aptitude was found to play a role in this variation for children in the classroom intervention condition. It was concluded that, with respect to initial lexical training, classroom-based intervention is associated with superior generalization of lexical targets to the home environment. Additionally, given differences in children's target word use in different settings, it was concluded that treatment progress data in isolation are not likely to provide complete information regarding children's lexical learning.

<tr>
<td>Baxendale &amp; Hesketh (2003)</td>
<td>Both direct (clinician to child) and indirect (clinician to caregiver) approaches are currently used in the management of children with language delay, but there is as yet little evidence about their relative effects or resources implications. This research project compared the Hanen Parent Program (HPP) in terms of its effectiveness and consequent suitability for an inner-city UK population with clinic-based, direct intervention. Thirty-seven children aged 2:6 to 3:6 years with a diagnosis of language impairment and their parents took part. The children were allocated on a geographical basis to receive therapy either as part of an HPP or in a clinic. The children’s language was assessed using the PLS-3 and from an analysis of audio-taped parent and child interaction at three assessment points, one pre therapy and two post therapy over 12 months. Two parent language measures were also analyzed. Significant gains in language scores were shown by 71% of the children over 12 months. There were no statistically significant differences in child language scores between the two therapy groups at any assessment point. However, the HPP was twice as intensive (in terms of therapist time) as clinic therapy based on average group size, which has resource implications. Results suggest that there are parent and child factors that need consideration when choosing an appropriate intervention program for a child with language impairment.</td>
<td>Participants were preschool age</td>

<tr>
<td>Bernhardt, Smith &amp; Smith (1992)</td>
<td>Evaluates a 2-yr collaborative language intervention program involving the parents, speech pathologist, and teachers of a 4-yr-old boy with a pervasive developmental disorder with autistic features. The intervention goals were trans-disciplinary, addressing specific communication development needs, as well as social, cognitive, and behavioral areas. Intervention strategies included both direct therapy sessions and indirect home/preschool facilitation. The subject developed some of the language and social skills necessary for preschool success and demonstrated greater communication skills, though they did not replace his acting out behaviors.</td>
<td>No experimental or quasi-experimental design (no control); did not address clinical question; participants were preschool age</td>
</tr>
<tr>
<td>Broen &amp; Westman (1990)</td>
<td>The effectiveness of parents as teachers of speech production skills was assessed by comparing changes in the phonological skills of their children, made during a period with no intervention, to changes that occurred when parents served as teachers, and by comparing those changes with changes that occurred in a contrast group who received no intervention. Twenty children, 12 in the experimental group and 8 in the contrast group, served as subjects. All children were between 4 and 5 years old at the beginning of the study. Parents were taught, in weekly sessions, to model, reinforce, and in other ways to teach their children. Both teaching goals and teaching materials were provided, and progress was monitored weekly. The speech production skills of children in the experimental group improved significantly when parents did the teaching. This was true for both within-subject</td>

<tr>
<td>Eiserman, Weber &amp; McCoun (1992)</td>
<td>This study investigates the appropriate roles of parents and speech-language pathologists in early intervention by longitudinally comparing the costs and effects of two programs for speech-disordered preschoolers: a home parent-training program and a clinic-based, low parent involvement program. Results from follow-up testing one year after the intervention ended corroborated the results immediately following intervention. Specifically, the home parent-training group performed at least as well as the clinic-based group on measures of speech and language functioning as well as on a measure of general development. On one variable measuring personal/social skills and one measuring adaptive behavior, the home parent-training group performed significantly better than the other group. Results of the cost analysis indicated that, excluding the value of parent time, there was no meaningful difference in program costs. The implications of this study are that parents can be given significant responsibilities in early intervention and that program administrators have the viable option of training parents to provide the primary early intervention services. Findings support the need for therapists to be trained to work with parents as well as with the child.</td>
<td>Participants were preschool age</td>
</tr>
<tr>
<td>Eiserman (1995)</td>
<td>This study, involving 40 preschool children with speech/language disorders, compared the costs and effectiveness of a home parent training intervention and a clinic-based, low parent involvement intervention. Longitudinal effects were comparable, supporting the feasibility of offering options to parents and the need for broadly trained interventionists.</td>
<td>Participants were preschool age</td>

<tr>
<td>Elder (1995)</td>
<td>Two major questions derived from social-interactional theory were addressed: What are the effects of an in-home communication training program for parents on (1) the acquisition of child-training skills (imitating/animating and expectant waiting) by parents of developmentally delayed children who have severe language impairments and autistic features and (2) the acquisition of communication behaviors in the children themselves? Questions regarding the social value of the intervention and effects on parent-child interactions were also addressed. Four mothers were taught two parent-training skills (imitating/animating and expectant waiting) during two in-home training sessions. Following the parent training, the mothers conducted training sessions in their homes with their children for 10 minutes, three times per week for 8-12 weeks. All sessions were videotaped and frequency counts</td>
<td>No SLP; does not directly compare training models; did not address clinical question</td>
</tr>
</tbody>
</table>
taken of the target parent skills and child target behaviors. A single subject experimental research design was used incorporating a multiple baseline across two parental child-training skills (i.e., imitating/animating, expectant waiting). Data were analyzed visually as is customary in single subject experimentation, and direct behavioral counts showed that all four mothers demonstrated increases in the frequency with which they used the child-training skills following treatment. Increases in four child behavior frequencies (i.e., vocal utterances, social responding, social initiating, and intelligible words spoken) were also noted. The ECO Scales Interaction Profile results supported direct behavioral count data, showing significantly improved parent-child interactions for the subject dyads over three conditions (p < .034). Additionally, Parental Consumer Satisfaction Questionnaire results indicated that the intervention was positively perceived by the parents. Furthermore, the utility of single subject experimentation procedures in clinical nursing practice was clearly demonstrated in this research, and the findings support nurse-conducted, in-home parent training as a practical and socially valid means of addressing the complex needs of chronically disabled children and their families.

<td>Gibbard, Coglan &amp; MacDonald (2004)</td>
<td>Parents and professionals can both play a role in improving children's expressive language development and a number of alternative models of delivery exist that involve different levels of input by these two groups. However, these alternative treatments have not been subject to rigorous comparative analysis in terms of both cost and clinical effectiveness. To compare, from the viewpoint of the healthcare provider, parent-based intervention (PBI) for preschool children presenting with expressive language delay with current practice observed in an actual healthcare setting where parents of the child follow a professional's advice on a review basis. Two groups of children were compared on a variety of expressive and receptive language assessment measures. One group (n=10) received standard individual general care. The comparison group (n=12) received PBI. After the 6-month study, the results indicated that children who received PBI made significantly greater language gains than children who received current practice. In addition, a cost-effective analysis was conducted. This showed that although the language gains delivered by PBI did incur some additional costs for the healthcare provider, there was no significant increase in cost per outcome gain over general care. Options in the implementation of PBI are discussed that could potentially save costs for the healthcare providers and increase the value of a PBI-based approach.</td>

<tr>
<td>Hemmeter &amp; Kaiser (1994)</td>
<td>Four parents were trained to use enhanced milieu teaching with their preschool children with developmental delays. The parents learned to use the strategies in the clinic and generalized them to the home. Positive effects were observed on children's spontaneous communication and target use, and on parent and child affect.</td>
</tr>
<tr>
<td>Howlin, Gordon, Pasco, Wade &amp; Charman (2007)</td>
<td>To assess the effectiveness of expert training and consultancy for teachers of children with autism spectrum disorder in the use of the Picture Exchange Communication System (PECS). Method: Design: Group randomized, controlled trial (3 groups: immediate treatment, delayed treatment, no treatment). Participants: 84 elementary school children, mean age 6.8 years. A 2-day PECS workshop for teachers plus 6 half-day, school-based training sessions with expert consultants over 5 months. Outcome measures: Rates of: communicative initiations, use of PECS, and speech in the classroom; Autism Diagnostic Observation Schedule-Generic (ADOS-G) domain scores for Communication and Reciprocal Social Interaction; scores on formal language tests. Controlling for baseline age, developmental quotient (DQ) and language; rates of initiations and PECS usage increased significantly immediately post-treatment (Odds Ratio (OR) of being in a higher ordinal rate category 2.72, 95% confidence interval 1.22-6.09, p &lt; .05 and OR 3.90 (95%CI 1.75-8.68), p &lt; .001, respectively). There were no increases in frequency of speech, or improvements in ADOS-G ratings or language test scores. The results indicate modest effectiveness of PECS teacher training/consultancy. Rates of pupils' initiations and use of symbols in the classroom increased, although there was no evidence of improvement in other areas of communication. Treatment effects were not maintained once active intervention ceased.</td>
</tr>
<tr>
<td>Iacono, Chan &amp; Waring (1998)</td>
<td>A group of five preschool children (ages 2.3-3.6 yrs) with developmental disability or Down syndrome and their mothers participated in a study into the efficacy of a parent-implemented language intervention. Each parent was included in the team as a consultee, with a speech pathologist and special educator acting as consultants within a collaborative consultation process. Treatment for each child was developed using this process, with specific strategies to increase language production skills decided by the team. Strategies were used within an interactive model of early language intervention. The effectiveness of treatment was determined within a multiple baseline design. For three children, the impact of treatment was evident, but the results were not replicated for the other two children. Descriptive analysis of mothers' communicative behaviours indicated that, following treatment, they tended to direct more utterances to their children, used more models, fewer questions and directives, and more (although limited) teaching strategies.</td>

<tr>
<td>--------------------</td>
<td>------------------</td>
</tr>
<tr>
<td>Kaiser (1995)</td>
<td>This study explored effects of teaching three novice trainers to teach three parents to implement milieu teaching with their preschool children who had language delays. Results demonstrated improved skills among trainers and increased use of the procedures by parents. Two of the three children showed increases in their targeted language responses following parents' milieu teaching.</td>
</tr>
<tr>
<td>Kaiser, Hancock &amp; Nietfeld (2000)</td>
<td>A study examined the effects of parent-implemented enhanced milieu teaching (EMT) on the language performance of children who have autism or pervasive development disabilities. Participants were six preschool children with autism and their mothers. Although results varied across individuals, overall results offered support for the effectiveness of naturalistic language interventions implemented by parents with children who have autism or pervasive development disabilities. Results revealed that parents can learn EMT procedures and generalize and maintain their use over time and across settings. Furthermore, results showed that children's social communication was enhanced across settings and measures.</td>
</tr>
<tr>
<td>Kaiser, Hemmeter &amp; Ostrosky (1996)</td>
<td>The purpose of this study was to evaluate the effectiveness of parent-implemented responsive interaction on the language and communication skills of preschool children with disabilities. Twelve parents participated in individual training sessions. A multiple baseline design across groups of families was used to evaluate the parents' use of the intervention strategies and the effects of the intervention on the children's language skills. Results indicated that all parents learned to use the procedures in the clinic setting and generalized their use of the procedures to interaction sessions conducted in the home. Although there was variability in child outcomes, positive effects were observed for all children. Maintenance sessions conducted 6 months after the end of training indicated that the parents had maintained their use of the procedures. In addition, changes in child language skills observed during intervention were maintained. All parents indicated that they were highly satisfied with their participation in the intervention and the effects of the intervention on the language and communication skills of their children.</td>
</tr>
<tr>
<td>Laski, Charlop, &amp; Shreibman (1988)</td>
<td>Parents of four nonverbal and four echolalic autistic children were trained to increase their children's speech by using the Natural Language Paradigm (NLP), a loosely structured procedure conducted in a play environment with a variety of toys. Parents were initially trained to use the NLP in a clinic setting, with subsequent parent-child speech sessions occurring at home. The results indicated that following training, parents increased the frequency with which they required their children to speak (i.e., modeled words and phrases, prompted answers to questions). Correspondingly, all children increased the frequency of their verbalizations in three nontraining settings. Thus, the NLP appears to be an efficacious program for parents to learn and use in the home to increase their children's speech.</td>

<td>Mobayed, Collins, Strangis, Schuster &amp; Hemmeter (2000)</td>
<td>A home-based interventionist effectively taught four mothers to embed the mand-model procedure in daily activities to teach expressive language skills to their young children with speech delays. During the intervention phase, parents were provided with feedback along with specific encouragement to use the individualized instructional program daily. The intervention resulted in children's acquisition of target verbal responses across settings.</td>
</tr>
<tr>
<td>Pierce &amp; Schreibman (1997)</td>
<td>A study involving two children (ages 7-8) with autism and eight typical peers investigated the efficacy of Pivotal Response Training implemented by multiple peers in enhancing social competency of children with autism. After treatment, the subjects engaged in high levels of interactions, initiations, varied toy play, and language use. Results support using peer trainers to promote social behavior in autism.</td>
</tr>
<tr>
<td>Rocha, Schreibman &amp; Stahmer (2007)</td>
<td>Young children with autism have deficits in initiating and responding to joint attention bids. This study was designed to examine a parent-implemented intervention targeting joint attention responding in children with autism. Parents were trained to increase their joint attention bids using behavior analytic techniques to facilitate appropriate responding. Parents effectively employed joint attention intervention techniques. As parent joint attention bids increased, children's responses increased. Children's joint attention initiations also increased, even though they were not direct targets of intervention. Findings suggest that parent behaviors during and after intervention impact generalization and maintenance of behavior changes.</td>
</tr>
<tr>
<td>Ruscello, Cartwright, Haines &amp; Shuster (1993)</td>
<td>A group of 12 preschool children with phonological process errors was selected, and individual subjects were randomly assigned to one of two treatments that differed in relation to service delivery. Group I received a treatment that was administered exclusively by the clinician. Group II received a combination that included clinician administered treatment and parent administered instruction with the Speech Viewer system. Results indicate that both groups improved significantly, but they did not differ significantly from each other in the degree of change. Implications with respect to the service delivery options and their respective components are discussed.</td>
</tr>
<tr>
<td>Schwartz, Anderson &amp; Halle (1989)</td>
<td>Four teachers of students with severe disabilities were taught to implement a naturalistic time delay procedure within their normal classroom routines to improve the language skills of their students. Following a short training program, the teachers increased their use of 3 types of opportunities for time delay. However, they required special training to capitalize on untrained opportunities for delay. Verbatim samples of the students' speech indicated that teachers of students with severe disabilities can be taught to use the time-delay procedure within their normal classroom routine and that their use of delay may have beneficial effects (e.g., increases in mean length of utterance, responsivity, and movement along a continuum of spontaneity) on the speech of their students.</td>

<tr>
<td>Seung, Ashwell, Elder &amp; Valcante (2006)</td>
<td>This retrospective study examined the efficacy of in-home father training on the communicative outcomes of children with autism. The in-home training consisted of two components: (1) expectant waiting; and (2) imitation with animation. Efficacy of parent training was examined by measuring the ratio of utterances produced by the parents to the utterances produced by the children and the number of verbal imitation by the parents. Outcomes of the children's verbal production were examined by measuring the number of (1) single word utterances; (2) different words produced; and (3) verbal response to questions. Following training there was a decrease in the ratio of parent to child utterances and an increase in (1) the use of imitation by the parents; and (2) the number of single words and different words produced by the children. Results of this study suggested that the parents had learned to wait for their children to communicate verbally during communicative interactions and to interact more efficiently with their children by using verbal imitation. Overall, the results of this study support the efficacy of parent training that focuses on promotion of social reciprocity, and have important implications for clinicians and future research.</td>
</tr>
<tr>
<td>Smith and Camarata (1999)</td>
<td>Naturalistic language teaching by teachers in consultation with language clinician. Examined the feasibility of an intervention using naturalistic language teaching procedures for communication problems of 3 children (aged 4-6 yrs) with autism conducted by the child's general education teacher in collaboration with the child's language clinician. The results of a multiple baseline study across children indicate successful implementation of naturalistic language teaching procedures in the school settings by all general education teachers and improved intelligibility of the language skills of all the children with autism in generalized spontaneous language use. These results are discussed in terms of previous research demonstrating the effectiveness and benefits of naturalistic teaching procedures and in terms of the implications for educational practices involving children with autism.</td>

<td>Barratt, Littlejohns &amp; Thompson (1992)</td>
<td>Forty two preschool children referred to a speech therapy department were randomly allocated to receive intensive individual speech therapy or the more traditional once weekly approach. Boys and minority ethnic groups were referred most frequently. Speech therapy improved expression more than comprehension, as measured on Reynell scales. The mean improvements were 0.5 SDs (95% confidence intervals (CI) 0.3 to 0.7) and 0.3 (95% CI 0.1 to 0.5) respectively. There was a greater improvement in children receiving intensive compared with weekly therapy in the expression scores (0.8 SDs (95% CI 0.5 to 1.1) v 0.2 SDs (95% CI -0.1 to 0.5]. White and non-white children had similar improvements in comprehension scores but white children had greater improvement in expression scores (1.1 SDs v 0.3 SDs). This difference was seen in both therapy groups.</td>
<td>Participants were preschool age</td>
</tr>
<tr>
<td>Handleman &amp; Harris (1983)</td>
<td>Four autistic, moderately retarded 5-6 yr olds were taught 4 sets of nonverbal imitation items under individual or paired (couplet) instruction conditions and were probed for generalization of their partners' responses. Results indicate that couplet training had a disruptive effect for 2 subjects as compared to one-to-one instruction. One subject learned responses faster when provided with couplet training than when instructed individually. The 4th subject displayed little difference between the 2 training conditions. In all cases, the percentage of partner's material learned during couplet instruction was consistently low. While one-to-one instruction may be effective for teaching basic skills, for some children these skills can be taught as well when they are paired with other students. Couplet training can also facilitate the transition of children to less restrictive environments.</td>

<tr>
<td>Jacoby, Lee, Kummer, Levin &amp; Creaghead (2002)</td>
<td>The present study was conducted to determine the average number of treatment units needed to achieve improvements in functional communication. The subjects, ages 3 to 6 years, consisted of 234 children who received speech-language pathology services over a two-year period at Children's Hospital Medical Center (CHMC) in Cincinnati, Ohio. Subjects had disorders of articulation and/or language and were rated on all areas of deficit using the ASHA functional communication measures (FCMs) of articulation/intelligibility, spoken language production, and spoken language comprehension. Results indicated that as the number of treatment units increased, the FCM level improved. These improvements were statistically significant for subjects with articulation/intelligibility and spoken language production disorders only. Younger children received the greatest benefit per units of therapy provided. Children with lower initial functional abilities generally required more units of therapy to demonstrate improvement than children with higher initial ability levels. Children with an associated factor, (i.e., anoxic brain damage, syndromes, hearing loss, etc.) generally required more units of therapy than those who had no other factors, although the results were not statistically significant. The majority of subjects (76.5%) improved by at least one FCM level following 20 hours or more of therapy. There was improvement of two FCM levels in 38.5%, and more than two levels in 18.5% of the overall group. The present study indicates that improvement in FCM abilities is made with treatment, and that the degree of improvement is correlated with the number of treatment units provided.</td>

Caveats to generalization:

Description of “inservice training” provided to SLP assistants not reported.

Average 38 sessions for each student.

Each student received between 90-120 minutes of intervention per week.

Each student received between 19 to 25 total hours of therapy “over a 15 week period”

Therapy targets (and therapy activities) differed across participants.

Study Limitations:

“Indirect” service narrowly defined as intervention from SLP assistants.

Not significant \( p = 0.005 \)

Amount of treatment more intensive for individual participants included comprehension monitoring, vocabulary development, grammar, and narratives.

Therapy targets (and therapy activities) differed across participants. “Indirect” service narrowly defined as intervention from SLP assistants.

Table 3. Results of systematic review.

Collaboration vs. Classroom-based Teacher – SLP independent vs. Pullout traditional
Classroom-based vs. Pullout

For students with speech/language impairments there were significant differences in vocabulary test gains between three service delivery groups (ANOVA p<.001). Duncan post hoc revealed that S/L impaired students in the collaborative setting made test gains significantly higher than those in both classroom-based and Pullout settings.

For students without speech/language impairments there were significant differences in vocabulary test gains between three service delivery groups (ANOVA p<.001). Duncan post hoc revealed that students without disabilities in the Classroom-based collaborative condition exhibited greater gains compared to children in the Classroom-based Teacher – SLP independent condition and children in Pullout traditional condition.

For students with no S/L service, both collaborative and classroom-based models increased vocabulary more than control group of vocabulary exposure from curriculum in classroom from teacher.

For students with speech/language impairments there were significant differences in vocabulary test gains between three service delivery groups (ANOVA p<.001). Duncan post hoc revealed that S/L impaired students in the collaborative setting made test gains significantly higher than those receiving vocabulary exposure in classroom from teacher.

Effect sizes calculated based on posttest means and standard deviations. Statistical significance was calculated and reported based on test

Study limitations:
Random assignment occurred only in classroom selection for comparing regular education students.
Confounding classroom and pullout service in classroom-based Collaborative group
Confounding individual and group therapy in pullout traditional group
Caveats to generalization:
Exactly how much time was spent on vocabulary curriculum in traditional condition not specified.
Treatment fidelity was not specifically measured but was discussed in frequent meetings.

Mean Age = Stated as “similar across groups”
M = not reported, F = not reported

N=177 (32 receiving speech-language services and 145 with typical speech-language skills)

Throneburg, Calvert, Slurm, et al. (2000)
### Study Summary Question 2

**Question 2:** What is the influence of the SLP service delivery model on functional communication?

Description of "inservice training" provided to SLP assistants not reported. Amount of treatment more intensive than in many US schools.

Therapy targets (and therapy procedures and activities in "Indirect" service narrowly defined as intervention areas identified by research. Specific intervention targets from SLP assistants for individual participants included comprehension monitoring, vocabulary development, grammar, and narratives.

Each student received between 19 and 25 total hours of therapy over a 15 week period.

Classroom group: Three years duration assumed; total amount of service not reported.

Pullout control group: Three years duration assumed; total amount of service not reported.

SLPs and SLP assistants used a therapy manual but included procedures and activities in intervention areas identified by research. Specific intervention targets for individual participants included comprehension monitoring, vocabulary development, grammar, and narratives.

Clinical Evaluation of Language Fundamentals (CELF-3) (UK) administered immediately post-treatment (T2) and at 12-month follow-up (T3).

Receptive: Individual vs. group (T2) Not significant
Individual vs. group (T3) Not significant

Explosive: Individual vs. group (T2) Not significant
Individual vs. group (T3) Not significant

"Indirect" service narrowly defined as intervention from SLP assistants.

Bland & Prelock (1995)
N=14, seven matched pairs with half in the LIC group and half in the Pullout group (matched by age, grade, and teacher observation), no gross neurological, physical, or cognitive problems; students with chronic ear infections or hearing loss excluded.

Mean age not reported but calculated as 7.11
M=9; F=5

Language disorders

Studying Summary Question 5

Boyle, McCarthy, Foxto, et al. (2007)
N=161 intended to treat; N=152 that completed study protocol
Age range corresponds to grades 1-6 in US

Grade Range = 1 to 4
Age Range = 6 to 9
Mean Age not reported but calculated as 7.11
M=9; F=5

Study limitations:

Make up of control groups (untreated and irregular outpatient service) do not allow direct comparison of efficacy or effectiveness of indirect (parent training) to direct (e.g., SLP training) service delivery models.

Another major limitation is that the cases and the control 2 are not comparable at follow-up (12 month difference) which means the ES should be interpreted with a great deal of caution.

Caveats to generalization:

Inadequate description of content and amount of training parents received.

Inadequate description of schedule and amount of home-based intervention parents provided to their children.

Other Measures:

- Number of phrases
- Number of morphemes
- Number of transformations
- Mean length of utterance

Diagnosed with autism and free from "inert neurological damage or other complicating factors such as dehciency"; IQ and language level assessed with psychometric and language tests (not specified)
